A new kind of nonlinear nonequilibrium patterns—twisted spiral waves—is predicted for periodically forced oscillatory reaction-diffusion media. We show, furthermore, that, in such media, spatial regions with modified local properties may act as traps where propagating waves can be stored and released in a controlled way. Underlying both phenomena is the effect of the wavelength-dependent propagation reversal of traveling phase fronts, always possible when homogeneous oscillations are modulationally stable without forcing. The analysis is performed using as a model the complex Ginzburg-Landau equation, applicable for reaction-diffusion systems in the vicinity of a supercritical Hopf bifurcation.

An important problem in the engineering of self-organized systems is how to control spontaneously formed waves and patterns. For the oscillatory Belousov-Zhabotinsky reaction, application of global periodic forcing was shown to produce various cluster patterns [1–3] and induce turbulent regimes [4]. In the experiments with catalytic CO oxidation on platinum, where bulk oscillations were unstable and spatiotemporal chaos spontaneously developed, application of periodic forcing allowed suppression of chemical turbulence, production of intermittent regimes with cascades of amplitude defects, and generation of oscillating cellular and labyrinthine patterns [5]. In both reactions, oscillations emerge through a Hopf bifurcation of a stationary uniform state and thus the observed behavior is characteristic for a broad class of systems. The universal description of reaction-diffusion systems near a supercritical Hopf bifurcation is provided by the complex Ginzburg-Landau equation [6]. The action of global periodic forcing on the systems described by this equation was first considered by Coullet and Emilsson [7,8]. Under sufficiently strong resonant $n:1$ forcing, oscillations are entrained and stationary or traveling $2\pi/n$-fronts become possible. The $2\pi$ phase fronts for the $1:1$ forcing are known as kinks (or phase slips). They represent traveling localized structures, because the states differing by the phase of $2\pi$ are physically identical. Therefore, as noticed in Ref. [8], they bear similarity with pulses in excitable media. Traveling $\pi$ fronts under $2:1$ forcing represent nonequilibrium Bloch walls [9]. Kinks and traveling Bloch walls are elementary wave patterns under forcing conditions. Instabilities of kinks lead to backfiring and development of intermittent regimes with reproduction of amplitude defects [10–12]. Transverse instabilities of nonequilibrium planar Bloch walls give origin to the Bloch turbulence [4]. In heterogeneous media near a Bloch-Ising transition, complex behavior due to reflections of Bloch waves on Ising domains has been found [13].

Here, our attention is focused on the properties of periodic trains formed by kinks or traveling Bloch walls. Our analysis reveals that, depending on the parameters of the oscillatory medium and the spatial period of a train, it can undergo a reversal of its propagation direction. We show how this phenomenon can be used to design traps for traveling kinks and Bloch walls. Furthermore, we find that a new kind of pattern—twisted rotated spiral waves—exists in oscillatory media under the conditions of front propagation reversal.

Under global resonant $n:1$ forcing, the complex Ginzburg-Landau equation (CGLE) for the slow complex oscillation amplitude $\eta$ is [7]

$$\dot{\eta} = (1 + i\nu)\eta - (1 + i\alpha)|\eta|^2\eta + (1 + i\beta)\nabla^2\eta + B(\eta^*)^{n-1},$$

(1)

where detuning $\nu = \omega_0 - \omega_c/n$ is determined by the natural ($\omega_0$) and forcing ($\omega_c$) frequencies and $B$ is the forcing amplitude. Oscillations are entrained by forcing in the parameter region known as the Arnold tongue [Fig. 1(a)]. Inside this region, kinks ($n = 1$) and Bloch walls ($n = 2$) traveling at a constant velocity are possible (see Refs. [7,10,11]). Moreover, wave trains formed by periodic sequences of such phase fronts can also be observed there.

Any traveling phase front is characterized by its chirality: “right” if the phase increases after front propagation and “left” if it decreases after that. A similar definition can be accepted for traveling wave trains. It is convenient furthermore to define the front velocity $V$ in such a way that it is always positive ($V > 0$) if a front propagates to increase the oscillation phase and negative ($V < 0$) otherwise. With this convention, all right fronts move at a positive velocity, while the velocity of any left phase front is negative. Note that the chirality is not defined for a standing front.

The velocity of an individual phase front is uniquely determined by the properties of the medium and the forcing parameters. For wave trains, it additionally depends on the spatial period $\lambda$ of a train. Figure 1(b) shows dependences $V(\lambda)$ for two different values of the coefficient $\beta$, obtained
For sufficiently small forcing amplitudes \( B \), the train velocity \( V(\lambda) \) can be analytically estimated. In this parameter region, the dynamics is approximately described [7] by the reduced equation for the local oscillation phase \( \varphi \),

\[
\dot{\varphi} = \nu - \alpha - B\sqrt{1 + \alpha^2 \sin\varphi + a(\nabla \varphi)^2 + b\nabla^2 \varphi},
\]

(2)

where \( \varphi = \phi + \arctan \alpha \) and \( \eta = \rho \exp(i\phi) \). For brevity, we have introduced here notations \( b = 1 + \alpha \beta \) and \( a = \alpha - \beta \). Note that such reduced phase description is justified, when \( b > 0 \) so that uniform oscillations are modulationally (Benjamin-Feir) stable. The kinks exist for \( B > 2\lambda \), where \( 2\lambda (\nu) = |\nu - \alpha|/\sqrt{1 + \alpha^2} \).

Applying the Cole-Hopf transformation \( \varphi = (b/a)\ln u \), this phase dynamics equation is transformed to a simple form analogous to the equation for front propagation in one-component bistable media [14],

\[
\partial_t u = Q(u) + b \partial_x u
\]

(3)

with the nonlinear function \( Q(u) = (a/b)u(\nu - \alpha - B\sqrt{1 + \alpha^2 \sin(n(b/a)\ln u)}) \). The roots \( u_j \) of equation \( Q(u) = 0 \) under the condition \( Q'(u_j) < 0 \) correspond to stable uniform locked states of the system. Explicitly, we have

\[
u_j = \exp\left[\frac{a}{nb} \arcsin\left(\frac{\alpha - \nu}{B\sqrt{1 + \alpha^2}}\right)\right].
\]

(4)

Although the system has an infinite sequence \( j = 1, 2, 3, \ldots \) of such roots, only \( n \) of them represent physically different phase-locked states.

A front train with spatial period \( \lambda \) is a solution of Eq. (3) satisfying periodicity conditions \( \varphi(x + \lambda/n) = \varphi(x) + 2\pi/n \) (for \( n > 1 \) one spatial period of the pattern consists of \( n \) subsequent \( 2\pi/n \)-fronts). In terms of the variable \( u \), these conditions take the form

\[
\varphi(x + \lambda/n) = \exp(2\pi a/nb)\varphi(x).
\]

(5)

Thus, the train solutions for \( u \) are not periodic, but grow exponentially with \( x \).

When propagation reversal occurs, a stationary train is possible. In the stationary case, Eq. (3) has the first integral

\[
(1/2)b(\partial_x u)^2 + W(u) = E,
\]

where \( W(u) = \int Q(u) du = (a/2b)u^2(\nu - \alpha + 2\alpha B\sqrt{1 + \alpha^2 [n(b\cos(n(b/a)\ln u)/a) - 2a\times\sin(n(b/a)\ln u)/a]}(4a^2 + n^2b^2)^{-1} - 1) \) and \( E \) is the integration constant. Using the periodicity condition (5) and the property \( W(u_{j+1}) = \exp(4\pi a/nb)W(u_j) \), we find that \( E = 0 \) for any stationary train. Thus, the wavelength \( \lambda_{st} \) of the stationary train is given by

\[
\lambda_{st} = \int_{u_j}^{u_{j+1}} \frac{b n^2}{2W(u)} du.
\]

(6)

This result does not depend on the choice of the root \( j \).
Solitary $2\pi/n$ phase fronts are front solutions of Eq. (3), such that $u(x, t) \to u_j$ for $x \to -\infty$ and $u(x, t) \to u_{j+1}$ for $x \to \infty$. They can be also viewed as a limit of a periodic train with $\lambda \to \infty$. According to Eq. (6), the wavelength of a stationary train diverges, if $W(u_j) = 0$. Solving this equation, we find that stationary solitary $2\pi/n$ fronts exist along the line $B = B_A(v)$ given by

$$B_{st} = \frac{1}{2a}(\alpha - \nu)\sqrt{\frac{a^2 + n^2b^2}{1 + \alpha^2}}.$$  

(7)

Note that, in the phase approximation, the boundaries of the Arnold tongue are $B = B_A(v)$. The line $B = B_{st}(v)$ is shown as the dashed line in Fig. 1(a). Along this line, the propagation direction of solitary phase fronts occurs. Phase fronts with the right chirality ($V > 0$) are found on the left side of this line, if $\beta > \alpha$.

As follows from (6), the condition for existence of stationary periodic trains is $W(u_j) < 0$. This means that they are found inside the region of the Arnold tongue, lying between the line $B = B_A(v)$ and the (nearest) boundary of the tongue [see Fig. 1(a)]. Such a region always exists if $b > 0$. For any given set of parameters, the wavelength of the stationary train can be computed by numerical evaluation of the integral in Eq. (6).

The above analysis shows that front propagation reversal occurs near any $n:1$ resonance. For $n = 1$, stationary kinks (i.e., $2\pi$ fronts) and periodic sequences of standing kinks are possible (the existence of stationary solitary kinks under global feedback conditions has previously been shown [10]). For $n = 1$, stationary $\pi$ fronts represent standing Bloch walls or their periodic sequences. Such standing structures are different from Ising walls, because the oscillation amplitude does not vanish here.

The wave propagation reversal can be induced by varying parameters of the medium. Most conveniently, this can be done by changing the coefficient $\beta$ in the CGLE, since this coefficient does not affect uniform oscillations and is only important for propagating waves.

The dependence of the wave propagation direction on the coefficient $\beta$ can be used to trap kinks and Bloch fronts. Such traps can be designed by creating spatial regions, where the coefficient $\beta$ is locally changed to reverse the propagation velocity. The left panel in Fig. 2 shows an example of a kink trap in the one-dimensional medium at the 1:1 resonance. The value of $\beta$ is decreased in the central region. No-flux boundary conditions are used in all our simulations. Initially, a rapid pacemaker operates at the left end of the medium. This pacemaker produces a kink train with a short spatial period. The train enters the modified central region and passes it with some deceleration. When the pacemaker is terminated, further kinks are not produced. However, the kinks inside the central modified region become trapped inside it and form a stationary pattern with a period corresponding to the velocity reversal. If the central heterogeneity is removed, the stored pulses would propagate out of it. The right panel in Fig. 2 demonstrates the trapping of Bloch fronts at the 2:1 resonance. The pacemaker at the left end of the medium produces a train of Bloch fronts.

Similar traps for kinks and Bloch fronts can also be constructed in two-dimensional media. The upper panel of Fig. 3 (see also video 1 in Ref. [15]) shows a series of snapshots where trapping of kinks by a central modified region is seen. A pacemaker in the lower left corner emits a kink train with a short spatial period. The first snapshot shows the kink train passing the rectangular-shaped inhomogeneity. Inside the inhomogeneity, the velocity of the kinks is decreased, resulting in a delay of the kinks at the upper right corner of the rectangle. In the second snapshot, the rear end of the kink train has reached the lower left boundary of the inhomogeneity. The kinks inside the inhomogeneity close to this boundary can no longer propagate and the kinks outside propagate around the central region. This leads to the formation of ring-shaped kinks in the upper right part of the inhomogeneity. As long as new

FIG. 3 (color online). Trapping of kinks and Bloch fronts in the two-dimensional medium. The coefficient $\beta$ is set to $\beta = 5$ and decreased to $\beta = 1.8$ in the rectangular central region. The medium parameters are the same as in Fig. 1. The system size is $1000 \times 1000$. Upper panel: Kink trap in 1:1 resonance. The snapshots of the spatial distribution of $\text{Re} \eta$ are taken at $t = 6000$, $t = 19000$ and $t = 32000$. Lower panel: Bloch wave trap in 2:1 resonance. Snapshots the spatial distribution of $\text{Re} \eta$ at $t = 2000$, $t = 16000$, and $t = 46800$ ($B = 0.061$).
kinks arrive, these rings collapse. When the kink train has passed the inhomogeneity, the stored kinks form stationary ring-shaped structures. In the lower panel of Fig. 3 (see also video 2 in Ref. [15]), trapping of traveling Bloch fronts at the 2:1 resonance is demonstrated. It proceeds similar to the respective process for the kinks near the 1:1 resonance. In our simulations, wave traps with various sizes and with complicated geometries could be created.

A special effect, related to kink propagation reversal, is the formation of twisted spirals near the 1:1 resonance in two-dimensional media [Fig. 4 (left panel)]. The central and outer parts in such a spiral are wound in opposite directions. These structures are stable, they are observed in numerical simulations starting with various initial conditions. A twisted spiral rigidly rotates as a whole, retaining its shape. In Fig. 4 (right panel), three subsequent snapshots of the spiral, separated by a third of the rotation period each, are superimposed (see also video 3 in Ref. [15]). We see that the instantaneous rotation center does not coincide with the location of the spiral tip. Instead, the oppositely wound central part of the spiral is steadily rotating. Thus, this regime can also be characterized as a kind of meandering. Qualitatively, the development of twisted spirals can be understood by noticing that the waves are tightly wound near the center and, therefore, their propagation direction should be reversed there. In the displayed simulation, the medium was characterized by negative dispersion ($\beta < \alpha$). Similar behavior has, however, been found by us in the simulations for the media with positive wave dispersion ($\beta > \alpha$) [16]. By changing the forcing intensity and frequency, winding and unwinding of the central part of the spiral can be controlled.

Our theoretical study has shown that, applying periodic forcing, one can induce propagation reversal of kinks, Bloch walls, and $2\pi/n$ phase fronts for higher resonances with $n > 2$. Using this effect, traps for propagating kinks and other phase fronts can be designed by creating appropriate heterogeneities in the medium. In our simulations, such heterogeneities were introduced by spatial variation of the coefficient $\beta$ in the CGLE, but similar effects can be achieved by varying other parameters of the medium or by applying inhomogeneous forcing. We have also shown that, in uniform media with 1:1 forcing, steadily rotating twisted spirals can develop. Though our results have been obtained only for the CGLE, we expect that they should be characteristic for a class of media where oscillations are not strongly relaxational. Our simulations using a realistic model of the catalytic surface reaction of CO oxidation on platinum have shown that the wave propagation reversal under periodic forcing takes place near a supercritical Hopf bifurcation in this reaction and that the wave traps can be constructed there [16]. Another experimental system where the predictions of our theory can be tested is the oscillatory photosensitive Belousov-Zhabotinsky reaction.
